Abstract: In this paper, we consider the problem of designing a distributed strategy to estimate the channel parameters for a generic Wireless Sensor-Actor Network (WSAN). To this aim, we present a distributed least-square algorithm that complies with the constraint of transmitting only integer data through the wireless communication, which often characterizes WSAN embedded architectures. In this respect, we propose a quantized consensus strategy that mitigates the effects of the rounding operations applied to the wireless exchanged floating data. Moreover, the approach is based on a symmetric random gossip strategy, making it suitable for the actual deployment in multiagent networks. Finally, the effectiveness of the proposed algorithm and of its implementation as an open-source application is assessed and the employment of the procedure is illustrated through the application to radio-frequency localization experiments in a real world testbed.

Keywords: Wireless sensor network; wireless channel modeling; consensus; quantized consensus; localization.

1. INTRODUCTION

In recent years, the academic community has devoted a huge research effort on distributed and network controlled systems, especially those employing mobile and wireless devices, such as, for example Wireless Sensor Networks (WSNs) or Wireless Sensor-Actor Networks (WSANs) (see for example Akyildiz and Kasimoglu (2004), Hespanha et al. (2007), Yick et al. (2008)).

In particular, when dealing with a radio-frequency (RF) wireless channel, it is of paramount importance to understand the properties of the wireless medium with respect to the specific network conditions. Beyond the main use of the wireless channel as a communication channel to transmit and share the information across the network, there are indeed many applications of localization and tracking where the distance among the nodes is inferred by the power level received by the same devices (see Cenedese et al. (2010) and references within).

Therefore, since the performance of any system based on RF wireless devices is strongly affected by the disturbances entering the communication channel, it is necessary to provide an accurate model of the transmission and to be able to detect the different contribution to path loss effects and power attenuation. With this scope in mind, in this work we aim at the design of a fully distributed algorithm that allows the network nodes to attain the identification of the channel model by their own without resorting to a central unit processing all the available information. A special attention is posed on the aspects of communication and quantization (Carli et al. (2010b)), which are particularly relevant in this scenario.

In summary, this work aims at providing a twofold contribution:

• on the theoretical side, a methodology for channel model identification that is completely distributed among the network nodes is studied with particular focus on the quantization effects;
• on the practical side, the experimental validation is presented and the implementation of the developed code is publicly available (Zanella (2013)).

The remainder of the paper is organized as follows: In Sec. 2 an overview of the state of the art on channel modeling and estimation is given, and in Sec. 3 the basic models of both the network and the transmission channel are described. Then, in Sec. 4 and Sec. 5 the main theoretical contribution are provided, respectively discussing the channel parameter identification and the proposed distributed approach to perform such procedure. In Sec. 6 the experimental results of the channel identification are shown and discussed, together with an application of localization and tracking. Finally, in Sec. 7 some conclusions are drawn.

2. RELATED WORK ON RF CHANNEL MODELING

In general, to understand the characteristics of radio transmission in a real world scenario, different approaches can be exploited, ranging from those exploiting a simulative
approach through ray-tracing numerical algorithms, to others relying on a defined channel model whose parameters need to be identified either in real-time or exploiting previously acquired experimental data (Valenzuela (1994), Kaya et al. (2009), Hashemi (1993)).

In the present work, it is considered the log-distance path loss model (Rappaport (2002)), where the received power is linked to the transmission power through a log-normal model of path loss, as better explained in Sec. 3. Despite the fact that the structure of the model is assumed, the values of its parameters are far from known, and characteristic of the installation environment (Wysocki and Zepernick (2000), Goldsmith (2005)), and thus, to employ the same model in different scenarios, a dedicated parameter tuning procedure can be implemented.

In this respect, one approach to parameter identification exploits centralized least square (LS) procedures that start from a series of measurements and compute the parameter set of the whole system. Such an approach (Durbin et al. (1998)) will be considered as a reference for this work and referred hereafter as Centralized Channel Parameter Identification (CCPI). Similar techniques are reported also in Ostesges et al. (2010), Bardella et al. (2010).

Differently, a solution here is sought that is distributed and can be implemented in a multiagent setup of limited resource devices, so as to make unnecessary the presence of special units or coordinating nodes. In this sense, a first distributed solution is proposed in Bolognani et al. (2010), where the consensus theory is applied to solve the global least-square optimization problem of parameter estimation. This solution is the base of the algorithm developed in this work (Distributed Channel Parameter Identification, DCPI).

3. SYSTEM MODEL

A sensor/actor network is commonly modeled as a graph $\mathcal{G} = (\mathcal{N}, \mathcal{E})$, where the ordered set $\mathcal{N} = \{1, \ldots, N\}$ of $N$ nodes communicate along the edges specified by the set $\mathcal{E}$. A graph $\mathcal{G}$ is called undirected when $(i, j) \in \mathcal{E} \Rightarrow (j, i) \in \mathcal{E}$. We denote with $\mathcal{V}(i) = \{ j \in\mathcal{E}, i \neq j \}$ the set of neighbors of node $i$, with the degree $d(i) = |\mathcal{V}(i)|$ its cardinality. We say that a graph is connected if every pair of nodes $(i, j)$ is connected by a path. In particular, a directed graph is called strongly connected if there is a path from each node in the graph to every other node.

The communication strategy among the nodes in the network can then fall into two categories: broadcast communication, where one node $i$ transmits a message to all its neighbors $\mathcal{V}(i)$, and gossip communication, where a node $i$ transmits a message to a specific node $j \in \mathcal{V}(i)$. The gossip communication can be either symmetric or asymmetric, respectively meaning that the transmitting node awaits for an answer from the receiver or not. In addition, the communication (broadcast or gossip) can be synchronous or asynchronous, and in the latter case the transmitting node sequence can be randomized or sequential. For more details, we refer the reader to the specialized literature (e.g. Mesbahi and Egerstedt (2010), Boyd et al. (2006)).

In our setup we consider a graph that is undirected, connected and not time-varying, in a randomized symmetric gossip type communication network.

In the particular case of a WSN/WSAN, nodes communicate through a wireless channel, which is characterized in general by a non-zero packet loss probability. The communication reliability through the wireless medium is affected by both static and dynamic phenomena, the former basically related to the environment structure, the latter mainly due to interference and noise. Considering two nodes $i$ and $j$, placed respectively at $z_i \in \mathbb{R}^3$, $z_j \in \mathbb{R}^3$ in an indoor environment, their distance being $d_{ij} := \|z_i - z_j\|_2$, a well agreed model is as follows, in terms of power $P_{ij}$ received by node $i$ when node $j$ is transmitting with $P_{tx}^j$:

$$P_{ij} := P_{tx}^j + r_{ij} + p_{fl}(d_{ij}) + f_{sf}(z_i, z_j) + f_a(z_i, z_j) + v_{ff}(t) + o_i,$$

where (all power levels are given in dBm):

- $r_{ij}$ and $o_i$ are the transmitter and receiver offsets (w.r.t. the datasheet value). Being basically related to manufacturing mismatches, they are supposed to be constant in time;
- $p_{fl}(\cdot)$ is the path loss effect. This term is the power attenuation of the transmitted signal as the source to receiver distance increases, and it is given by a log-distance model Rappaport (2002):

$$p_{fl}(d_{ij}) := \beta - 10\gamma \log_{10}(d_{ij}) :$$

where $\beta$ is the receiver gain at the the nominal distance $d_{ij} = 1 \text{ m}$ and $\gamma$ is the loss factor;
- $f_{sf}(\cdot)$ is the slow fading component due to the effects of large obstacles along the propagation path (shadowing); it is supposed to be space dependent, symmetric, and modeled as a Gaussian variable (Gudmundson (1991));
- $f_a(\cdot)$ is the channel asymmetry factor. Related to signal non-symmetric reflections, it is spatially modeled as a zero-mean Gaussian random noise;
- $v_{ff}(\cdot)$ is the fast fading. This contribution is due to fast signal fluctuations, therefore it can be modeled as temporal zero-mean white noise.

4. CENTRALIZED PARAMETER IDENTIFICATION

The parameters of the Eq. (1) depend on the properties of both the environment where the network is installed and the specific hardware in use, and they need to be estimated on site, during a dedicated learning phase or continuously during runtime. In this perspective, the model of Eq. (1) is simplified by taking the following assumptions:

- the transmission power of the sensors is set at the maximum level, $P_{tx}^i = 0$ dBm, $\forall j \in \mathcal{N}$, so that the transmitter offset is almost zero, $r_{ij} \cong 0$ dBm;
- the offset $o_i$ is assumed to be zero, $\forall i \in \mathcal{N}$. Beside being an approximation, we want to notice that the offsets can be compensated exploiting a distributed strategy (Bolognani et al. (2010)) that is completely decoupled from the channel parameter estimation;
- the fast fading effect $v_{ff}(t)$ is removed, by averaging the received power over a set of $M_{ij}$ > 0 consecutive measures:

$$P_{ij} := \sum_{k=1}^{M_{ij}} p_k.$$ 

It follows that the average received power $P_{ij}$ becomes:

$$P_{ij} = \beta - 10\gamma \log_{10}(d_{ij}) + f_{sf}(z_i, z_j) + f_a(z_i, z_j).$$
Moreover, the components of slow fading and channel asymmetry are independent Gaussian random variables of variance $\sigma_i^2$ and $\sigma_j^2$ respectively and can be combined into one zero-mean random variable $w_{ij}$ with variance equal to 
\[ \sigma^2 = \sigma_i^2 + \sigma_j^2. \] 

(4) 

Such a channel model requires only the estimation of $\beta$ and $\gamma$. Hence, we can write the model in linear form and employ a LS estimator: being a Markov estimator, this will coincide with the maximum likelihood estimator.

For each sensor $i \in N$ we collect the self positions $z_i$ communicated by neighbors $j \in \mathcal{V}(i)$, which allows the computation of the relative distance $d_{ij}$, and $M_{ij}$ measurements of the received power $P_{ij}$ to evaluate the average $\overline{P}_{ij} = \sum_{k=1}^{M_{ij}} P_{ij}^k$. We define $D(i) := \{|\{\overline{P}_{ij}, d_{ij}\} | j \in \mathcal{V}(i)\}$ as the actual data set available to each sensor $i$, and the communication flow is equal to $\sum_{j=1}^{N} \sum_{i \in \mathcal{V}(i)} M_{ij}$ to finally collect $M := \sum_{i=1}^{N} |D(i)|$ total data pairs.

Starting from these $M$ measurements, consider the linear regression model $b = S\theta + w$, where $\theta := [\beta, \gamma]^T$ is the parameter vector to be estimated, $w$ is a $M$-dimensional zero-mean random vector with variance $\sigma^2 I = (\sigma_i^2 + \sigma_j^2)I$, and $b$ and $S$ are defined as 

\[
\begin{bmatrix}
\overline{P}_{1j_1} \\
\vdots \\
\overline{P}_{ij_{(M_{ij})}} \\
\overline{P}_{Nj} \\
\vdots \\
\overline{P}_{Nj_{(Nj)}} \\
\end{bmatrix}, \\ S := 
\begin{bmatrix}
1 & -10 \log_{10} d_{1j_1} \\
\vdots \\
1 & -10 \log_{10} d_{ij_{(M_{ij})}} \\
\vdots \\
1 & -10 \log_{10} d_{Nj} \\
\vdots \\
1 & -10 \log_{10} d_{Nj_{(Nj)}} \\
\end{bmatrix}
\]

Under this assumption it is well known (Rao et al. (1997)) that the LS identification of the parameter $\theta$ is given by: 
\[ \hat{\theta}_{CCPI} := \arg \min_{\theta} \|S\theta - b\| = (S^TS)^{-1}S^Tb \] 

(5) 

with variance $N^{-1}\|b - S\hat{\theta}_{CCPI}\|^2$, assuming that the matrix $S^TS$ is not singular.

This approach is referred to as Centralized Channel Parameter Identification (CCPI).

5. DISTRIBUTED PARAMETER IDENTIFICATION
A strategy is now presented to distributedly estimate the parameters $\beta$ and $\gamma$ of the communication channel in (4). Consider a network of $N$ nodes endowed with a state $x_i(t) : \mathbb{R} \to \mathbb{Z}$, $\forall i \in N$. The consensus problem can be summarized as the problem of allowing the nodes to reach an agreement regarding a quantity that is function of the state of all nodes. A consensus algorithm is an interaction rule of the form 
\[ x_i(t+1) = Q(t)x_i(t), \] 

(6) 

where $x_i(0)$ is given, $x_i(t) = [x_i(t), \ldots, x_N(t)]^T \in \mathbb{R}^N$ and $Q(t) \in \mathbb{R}^{N \times N}$. Specifically, with reference to a randomized symmetric gossip communication, $Q(t)$ is a random matrix extracted from an i.i.d. sequence $\{Q(t)\}_{t \geq 0}$ of double stochastic matrices, defined as 
\[ Q(t) = I - \frac{1}{2}(e_i - e_j)(e_i - e_j)^T \] 

where $e_i = [0 \ldots 0 1 0 \ldots 0]^T \in \mathbb{R}^N$ is a null vector except for the $i$-th component that is equal to 1; the couple $(i, j)$ refers to the randomly selected edge at time instant $t$. Notice that when a link $(i, j)$ fails in a symmetric gossip, there is no communication at all and then no update is performed ($Q(t) = I$ for some $t$). According to the previous statements, the system in (6) can be rewritten as 
\[
\begin{cases}
x_i(t+1) = x_j(t+1) = \frac{1}{2}(x_i(t) + x_j(t)) \\
x_h(t+1) = x_h(t) \quad \text{if } h \neq i, j
\end{cases}
\] 

(7)

From (Boyd et al. (2006)) we know that given an i.i.d. sequence $\{Q(t)\}_{t \geq 0}$ of doubly stochastic matrix and a connected graph in which each edge is selected with a strictly positive probability, then, for every initial condition $x(0)$, the sequence $\{Q(t)\}_{t \geq 0}$ solves the probabilistic (average) consensus problem. That is, almost surely 
\[ \lim_{t \to \infty} x_i(t) = \frac{1}{N} \sum_{i=1}^{N} x_i(0) = \frac{1}{N} 1_N x(0) \quad \forall i \in N. \] 

(8)

Notice that the presented strategy and assumptions allow to accept link failures during the communication process.

5.1 Quantized Consensus
The gossip algorithm in (7) is based on the crucial assumption that each node transmits to its neighbor the exact value of its state, but sometimes the quantization of the messages is practically imposed by communication constraints, application features or specific programming languages. This happens for example in TINYOS (Lewis (2006)), an open source operating system specially designed for WSNs, whose transmission protocol forces to use integer numbers (obtained by round operation). Because of this, nodes transmit measurements (i.e. their states) that differ from the actual values, and thus they have a knowledge about the neighbors’ states that is not precise. This behavior can be assimilated to a quantization scheme and Carli et al. (2010a) have investigated the adaptation of the gossip algorithm to a network subject to quantized communication. In this scenario, our aim is to present and discuss what kind of quantization is convenient to adopt.

We define deterministic quantizer a map $q_d : \mathbb{R} \to \mathbb{Z}$ that converts a number $v \in \mathbb{R}$ into its nearest integer, i.e.
\[ q_d(v) = n \in \mathbb{Z} \iff \begin{cases} v \in -n + \frac{1}{2} \quad & \text{if } v \geq 0 \\ v \in -n + \frac{1}{2} \quad & \text{if } v < 0 \end{cases} \] 

(9)

Instead, we call standard probabilistic quantizer the map $q_p : \mathbb{R} \to \mathbb{Z}$ that, for any $v \in \mathbb{R}$, is defined by
\[ q_p(v) = \begin{cases} [v] & \text{with probability } [v] - v \\ [v] & \text{with probability } v - [v] \end{cases} \] 

(10)

Now assume that $(i, j)$ is the edge selected at time $t$. Considering the deterministic and standard probabilistic quantizer, sensors $i$ and $j$, following the update rule in (7), apply the algorithms 
\[ x_i(t+1) = x_j(t+1) = \frac{1}{2}(q_d(x_i(t)) + q_d(x_j(t))) \] 

(11)
\[ x_i(t+1) = x_j(t+1) = \frac{1}{2} (q_p(x_i(t)) + q_p(x_j(t))) . \] (12)

It has been proved that the laws (11)-(12) drive the systems almost surely to consensus at an integer value, i.e. almost surely there exist \( T \in \mathbb{Z}_{\geq 0} \) and \( \bar{x} \in \mathbb{Z} \) such that \( x_i(t) = \bar{x} \), for all \( i \in \mathcal{N} \) and for all \( t \geq T \). The previous statement highlights how these strategies don’t preserve in general the initial average, but it can be proven that with the standard probabilistic quantizer it is at least guaranteed that the average is preserved in expectation. We compare here the quantization strategies (11) and (12) in terms of the deviation
\[
\bar{x} = \mathbb{E}[\mathbb{E}[\mathbb{E}[\mathbb{E}[\mathbb{E}[x(t+1)|x(t)|]|x(t+1)|x(t)|]|x(t+1)|x(t)|]|x(t)|].
\] (13)

In Fig. 1(a), \( \bar{x} \) is plotted as a function of the number of sensors, i.e. generating complete graphs of increasing size, with random topology. Simulations show that using a \( q_p \) quantization the reached consensus is close to the average of the initial condition, although the average is preserved only in expectation. On the contrary, due to the accumulation of rounding errors, a \( q_d \) approach leads to a consensus point which is remarkably distant from the average of the initial condition. Moreover, this gap increases with \( N \) and depends on the initial condition.

In Fig. 1(b) we consider again the strategy
\[ x_i(t+1) = x_j(t+1) = \frac{1}{2} (q_u(x_i(t)) + q_u(x_j(t))) \] (14)
where \( q_u \) represents a generic quantization, as in (11)-(12). We compare different deterministic and probabilistic quantizers, in terms of the quantization error \( \bar{x} \) (13) as a function of the length of initial condition range \( L = 2x_0 \), where \( x(0) \sim U([-x_0 x_0]), x_0 \in [0 100], x_0 \in \mathbb{Z} \). The setup is given by a random graph built on a set of \( N = 30 \) sensors. To apply the strategy in (14), we select a deterministic quantizer \( q_d \), a ceiling deterministic quantizer \( q_{u} (v) := \lceil v \rceil \), a flooring deterministic quantizer \( q_{d} (v) := \lfloor v \rfloor \), a uniform probabilistic quantizer
\[
q_u(v) = \begin{cases} \lfloor v \rfloor & \text{if } P[v(0,1) > 0.5] \\ \lceil v \rceil & \text{otherwise} \end{cases}
\]
and a gaussian probabilistic quantizer
\[
q_d(v) = \begin{cases} \lfloor v \rfloor & \text{if } P[v(0,1) > \lambda] \\ \lceil v \rceil & \text{otherwise} \end{cases}
\]
Simulations show that the quantizers lose their independence from initial conditions and they increase their \( \bar{x} \) error as they become more deterministic. It is clear from the plots reported in Fig. 1(b) that a rounding operation is better than using only a \( q_u \) and \( q_d \) quantizers (which are clearly comparable) since it switches between the ceiling and flooring of the state following the rule defined in (9).

A \( q_u \) quantizer, which chooses to ceil or floor the state with a Gaussian probability becomes less deterministic as the \( \lambda \)-threshold moves from the mean of the Gaussian distribution. It is easy to see that the uniform probabilistic quantizer is best quantizer in terms of both independence from initial conditions and negligible \( \bar{x} \) error. The reason is that the \( q_u \) quantizer chooses with uniform probability to apply a ceiling or flooring rule, hence its randomness is higher than all the other strategies considered.

### 5.2 Least-squares estimation via consensus

The Distributed Channel Parameter Identification (DCPI) through a consensus approach is a procedure discussed in Bolognani et al. (2010). The LS estimation of the channel parameters can be computed as the solution of a distributed algorithm that does not require the knowledge of the total number of nodes \( N \) or the total number of data \( M \) available. Here we build on this result to design a formulation combined with the quantization procedure, which is suitable for our goal.

Consider
\[
\mathbf{b}_i := \begin{bmatrix} \mathbf{P}_{ij}^{(i)} \end{bmatrix} \text{ and } \mathbf{S}_i := \begin{bmatrix} 1 & -10 \log_{10} d_{ij} \end{bmatrix} ,
\]
as the blocks of size \( |D(i)| \) of \( \mathbf{b} \) and those of size \( |D(i)| \times 2 \) of \( \mathbf{S} \), introduced in Sec. 4, and compute
\[
\mathbf{\tilde{S}}_i := \mathbf{S}_i^T \mathbf{b}_i = \begin{bmatrix} |D(i)| & -10 \sum_{k=1}^{|D(i)|} \log d_{ik} \\ -10 \sum_{k=1}^{|D(i)|} \log d_{ik} & 100 \sum_{k=1}^{|D(i)|} (\log d_{ik})^2 \end{bmatrix}
\] (15)
and
\[
\mathbf{\tilde{b}}_i := \mathbf{\tilde{S}}_i^T \mathbf{b}_i = \begin{bmatrix} \sum_{k=1}^{|D(i)|} \mathbf{P}_{ik}^{(i)} \end{bmatrix} .
\] (16)

In this way, each component of the matrices \( \mathbf{\tilde{S}} \) and vectors \( \mathbf{\tilde{b}} \) can be computed independently, i.e. six different consensus procedures can be applied at the same time to distributively compute the matrices components that yield the identification of the channel parameters. In fact:
\[
\hat{\theta}_{CCPI} = (\mathbf{S}^T \mathbf{S})^{-1} \mathbf{S}^T \mathbf{b} = (\frac{1}{N} (\mathbf{S}^T \mathbf{S}))^{-1} \frac{1}{N} (\mathbf{S}^T \mathbf{b})
\]
\[
= (\frac{1}{N} \sum_{i=1}^{N} \tilde{S}_i)^{-1} (\frac{1}{N} \sum_{i=1}^{N} \tilde{b}_i) =: (\mathbf{\bar{S}})^{-1} \mathbf{\bar{b}},
\]
where \( \mathbf{\bar{S}} \) and \( \mathbf{\bar{b}} \) have been introduced to simplify the notation. By introducing state \( X_i \) as the unknown channel parameters \( X_i := [\tilde{S}_i | \tilde{b}_i] \), the consensus strategy with uniform quantization can be applied to the node pair \( (i,j) \)
\[
\begin{align*}
X_i(t+1) &= X_j(t+1) = q_u \left( \frac{1}{2} (X_i(t) + X_j(t)) \right) \\
X_h(0) &= [\tilde{S}_h | \tilde{b}_h] & \forall h = i,j
\end{align*}
\] (17)
After a finite time \( T \) the nodes reach consensus over the elements \( \mathbf{\bar{S}} \) and \( \mathbf{\bar{b}} \), which are needed for the distributed channel identification, i.e.
\[
\forall h = 1, \ldots, N, \text{ where } \mathbf{E} \text{ and } \mathbf{e} \text{ are the (bounded) errors introduced by the quantization performed at each iteration. Hence, the DCPI is given by}
\]
\[
\hat{\theta}_{DCPI} = (\mathbf{S} + \mathbf{E})^{-1} (\mathbf{E} + \mathbf{e}) .
\] (18)

By the Matrix Inversion Lemma (Tylavsky and Sohie (1986)), assuming that \( \mathbf{E} \) is non-singular, the identity
\[
(\mathbf{S} + \mathbf{E})^{-1} = (\mathbf{S})^{-1} - (\mathbf{S})^{-1}(\mathbf{E})^{-1} + (\mathbf{S})^{-1}(\mathbf{S}^{-1} - (\mathbf{S})^{-1})(\mathbf{S})^{-1}
\]
is used to rewrite (18) as
\[ \hat{\theta}_{DCPI} = (S)^{-1} \mathbf{B} + \bar{\epsilon} = \hat{\theta}_{CCPI} + \bar{\epsilon} \]
meaning that the distributed estimation corresponds to its
centralized version corrupted by a bounded additive error
that depends on the quantization errors on \( E \) and \( e \):
\[ \bar{\epsilon} = (S)^{-1} \left[ e - (1 - ((E)^{-1} + (S)^{-1})^{-1}(S)^{-1}) (\mathbf{B} + e) \right]. \]

6. EXPERIMENTAL RESULTS

The strategy described in the previous sections have been
assessed and validated by implementing the algorithms on a
TmoteSky WSN installed at the ground floor of
the Department of Information Engineering (DEI) of the
University of Padova. This area, shown in Fig. 2, has an
approximate size of 15 \( \times \) 36 m\(^2\), is partially unstructured,
with laboratory/office furniture and equipment, and is subject
to a reasonable level of interference and electromagnetic
noise.

![Planimetry of the testbed (WSN layout).](image)

6.1 Quantization effects

Before dealing with the channel identification procedure,
the efficacy of the symmetric gossip communication is
assessed by testing the deterministic version described
by (9). A subset \( N = \{s_1, \ldots, s_N\} \) of fixed sensors is
considered, placed in arbitrary positions but in a range
such that each sensor \( s_j \in N \) can communicate with at
least another \( s_j \in N \). A state value \( x_i(0), i = 1, \ldots, N, \) is
then assigned to each of these sensors, and simulations are
performed gradually increasing \( N \) and assigning suitable
values to the timings and to the desired percentage of
collision probability, to converge much faster without com-
promising the final outcome. The simulations (reported
in Cenedese and Zanella (2014)) confirm the convergence
towards a common value that does not coincide exactly
with the expected value \( \bar{x} \) because of the behavior of the
deterministic quantizer, as stated in Sec. 5.

Again, with a configuration example of \( N = 7 \) nodes
in a random connected graph (taken in the dashed red box highlighted in Fig. 2), it can be assessed that a
symmetric gossip with probabilistic quantizers is generally
better than a deterministic one, by comparing \( q_d \) and \( q_u \)
quantizers for different initial conditions \( x_i(0) \) of the scalar
state \( x_i(t), i = 1, \ldots, N \). Fig. 3 shows the consensus errors
\( \tilde{x}_d := \|x_d - N^{-1}\mathbf{1}\mathbf{x}(0)\| \) and \( \tilde{x}_u := \|x_u - N^{-1}\mathbf{1}\mathbf{x}(0)\| \), for
different lengths of the initial condition range \( L = 2x_0 \),
where \( \mathbf{x}(0) \sim U([-x_0 \; x_0]) \), and \( \tilde{x}_d, \tilde{x}_u \) are the consensus
values reached by the two quantizers. It is easy to see that
in the considered cases \( \tilde{x}_u \) is almost always lower than \( \tilde{x}_d \).

6.2 DCPI algorithm

Then, the distributed identification of the \( \beta \) and \( \gamma \) par-
eters of the channel model is carried out by means of the
symmetric gossip algorithm of Sec. 5.

It is important to observe that the procedure requires the
node synchronization because the algorithm consists of
a unique phase in which the sensors perform the power
measurements needed to build consensus matrices (15)
and (16). Alternatively, the synchronization requirement
can be removed by modifying the algorithm in such a way
that each node can make Received Signal Strength (RSS)
requests to the WSN even when other nodes have already
started the consensus iterations. Consider the matrix $X_i(t)$ of the consensus strategy (17):

$$X_i(t) = \left[ \bar{S}_i(t) | \bar{b}_i(t) \right] = \begin{bmatrix} x_i^{(1,1)}(t) & x_i^{(1,2)}(t) & x_i^{(1,3)}(t) \\ x_i^{(2,1)}(t) & x_i^{(2,2)}(t) & x_i^{(2,3)}(t) \\ \vdots & \vdots & \vdots \end{bmatrix} :$$

the trajectories of the entries $x_i^{(h,k)}(t)$ converge, some of these showing an oscillatory behavior for a limited period of time, due to the quantization effect that causes the node states to randomly oscillate around nearby values (see Cenedese and Zanella (2014)).

To compare the performance of the DCPI with that of the CCPI, a set of 20 experimental RSS measurements for a subset of nodes has been collected by a centralized server communicating through wired connection with the tested nodes (thus the data in this case are not quantized). The $\hat{\theta}_{CCPI}$ parameters are computed through (5) for the tested environment, obtaining $L = 2r_0$, where $x(0) \sim U([-x_0x_0])$, $x_0 \in \{1/2, 11/2, \ldots, 91/2\}$.

Experiments with different paths in the environment have been studied (an example is reported in Fig. 5) and the localization problem is solved here using the algorithm described in Bertinato et al. (2008) and based on the channel model considered in this paper. In short, this algorithm applies a maximum-likelihood method to estimate the distances of a mobile node in a network of fixed nodes (where the neighbors of the former dynamically change during the motion) by basically inverting the relation of Eq. 4. Then, the algorithm computes a LS estimation of the position of the mobile node by exploiting the estimated distances.

Experiments with different paths in the environment have been studied (an example is reported in Fig. 5) and the mean localization error is computed as

$$\frac{1}{K} \sum_{k=1}^{K} ||\hat{z}_0(k) - z_0(k)||,$$

where $z_0(k) = [x_0(k), y_0(k)]$ is the real position in the $\mathbb{R}^2$ plane of the mobile sensor and $\hat{z}_0(k)$ is the estimated position of the mobile sensor returned by the localization process in each $k = 1, \ldots, K$ time steps.

Fig. 3 shows the two channel models, described analytically by $P(r) = d - 10^\beta \log_{10}(d)$ as a function of the distance $d$. Although the parameters identified through the two procedures differ in the absolute values, interestingly the two models are very close in the range of higher interest ($d \in [3, 9]$). This consideration justifies the possible employment of the DCPI in practical WSN applications, where the distributed technique may result more suitable for the less demanding requirements (in terms of transmission policy, communication flow, computational burden) with respect to the centralized approach. In particular, the advantage of using a distributed approach is clear when considering the communication burden, which affects also the energy consumption: both these issues are of paramount importance in networked systems composed by limited resource embedded devices.
This observation also hints at the local nature of the channel model and promotes the employment of a local identification procedure apt for a distributed approach. Indeed, the localization experiments support the idea that this distributed approach can be adopted in similar applications to get the parameters describing communication channel, thus avoiding the use of a centralized method.

7. CONCLUSIONS

In this work, a distributed procedure to identify the parameters of a RF-channel model is proposed. The approach resorts to a quantized consensus algorithm, where different kind of quantizers are compared and discussed.

A set of validation experiments are then conducted, both in simulation and in a real experimental setup, to assess the quantized distributed procedure. In particular, for the real scenario experiments, the channel identification procedure is applied to the RF-based localization problem, whose performance is strongly affected by a correct modeling of the channel.

The results of these experiments prove the validity of the distributed approach for channel modeling as proposed in the paper and show consistency with the centralized identification, while being beneficial in terms of resource requirements with respect to the centralized approach.

Future works will focus on a more comprehensive and quantitative comparison between the CCPI and DCPI approaches, and a deeper study on the deviation error bounds for each quantization method.
